

MC1569 MC1469

Specifications and Applications Information

MONOLITHIC VOLTAGE REGULATOR

The MC1569/MC1469 is a positive voltage regulator designed to deliver continuous load current up to 500 mAdc. Output voltage is adjustable from 2.5 Vdc to 37 Vdc. The MC1569 is specified for use within the. military temperature range (—55 to +125°C) and the MC1469 within the 0 to +70°C temperature range.

For systems requiring a positive regulated voltage, the MC1569 can be used with performance nearly identical to the MC1563 negative voltage regulator. Systems requiring both a positive and negative regulated voltage can use the MC1569 and MC1563 as complementary regulators with a common input ground.

- **Electronic "Shut-Down" Control**
- **Excellent Load Regulation (Low Output Impedance 20 milliohms typ)**
- **High Power Capability: up to 17.5 Watts**
- **Excellent Temperature Stability: ±0.002% /°C typ**
- **High Ripple Rejection: 0.002%/V typ**

M C 1569, MC 1469 (continued)

- **Note 1. "Minimum Input Voltage" is the minimum "total instantaneous input voltage" required to properly bias the internal zener reference diode. For output voltages greater than approximately 5.5 Vdc the minimum "total instantaneous input voltage" must increase to the extent that it will always exceed the output voltage by at least the "input-output voltage differential".**
- Note 2. This parameter states that the MC1569/MC1469 will
regulate properly with the input-output voltage differ-
ential (V_{in} V₀) as low as 2.7 Vdc and 3.0 Vdc respec-
tively. Typical units will regulate properly wi V_0) as low as 2.1 Vdc as shown in the typical column. **(See Figure 21.)**
- **Note 3. "Temperature Coefficient of Output Voltage" is defined as:**

MC1569, TC_{V_O} =
$$
\frac{\pm (V_0 \text{ max} - V_0 \text{ min}) (100)}{(180^0 \text{C})(V_0 \otimes 25^0 \text{C})} = %10^0 \text{C}
$$

M C1469, TC_{V_O} =
$$
\frac{\pm (V_{o max} - V_{o min}/1100)}{(75^0C)(V_{o} \otimes 25^0C)} = \frac{100}{15^0C}
$$

The output-voltage adjusting resistors (R1 and R2) must have matched temperature characteristics in order to maintain a constant ratio independent of temperature.

Note 4. The input signal $(v_{in} \approx 1.0 \text{ V}$ [rms]) can be introduced **by use of a transformer which will allow the output of an audio oscillator to be coupled in series with the dc**

input to the regulator. (See Figure 20.) Input regulation is the percentage change in output voltage per volt change in the input voltage and is expressed as

Input Regulation =
$$
\frac{\Delta V_0}{V_0 \left(\Delta V_{in}\right)}
$$
 100 $(\% / V_{in})$.

where ΔV_Q is the change in the output voltage V_Q for the input change ΔV_{in} .

Note 5. Load regulation is specified for small (\leq +17^oC) changes **in junction temperature. Temperature drift effect must be taken into account separately for conditions of high junction temperature changes due to the thermal feedback that exists on the monolithic chip.**

$$
\text{Load Regulation} = \frac{[V_0|_{L} = 1.0 \text{ mA}]}{V_0|_{L} = 1.0 \text{ mA}} \times 100
$$

Note 6. The resulting low level output signal (v_o) will require the **use of a tuned voltmeter to obtain a reading. Special care should be used to insure that the measurement technique does not include connection resistance, wire resistance, and wire lead inductance (i.e., measure close to the case). Note that No. 22 AWG hook-up wire has approximately 4.0 milliohms/in. dc resistance and an inductive reactance of approximately 10 milliohms/in. at 100 kHz. Avoid use of alligator clips or banana plugjack combination.**

GENERAL DESIGN INFORMATION

-
- **1. Output Voltage, V 0 a) For V 0 3.5 Vdc Output voltage is set by resistors R1 and R2 (see Figure 4). Set R2 = 6.8 k ohms and determine R1 from the graph of Figure 10 or from the equation:**

$$
R1 \approx (2 V_{\rm g} - 7) k\Omega
$$

b) For $2.5 \le V_0 \le 3.5$ Vdc $-$ Output voltage is set by resis**tors R1 and R2 (see Figure 5). Resistors R1 and R2 can be determined from the graph of Figure 11 or from the equations:**

$$
R2 \approx 2 (V_0) k\Omega
$$

$$
R1 \approx (7 k\Omega - R2) k\Omega
$$

- c) Output voltage, V_O, is determined by the ratio of R1 and **R2, therefore optimum temperature performance can be achieved if R1 and R2 have the same temperature coefficient.**
- **d) Output voltage can be varied by making R1 adjustable as shown in Figure 43.**
- **e) If V 0 = 3.5 Vdc (to supply RTL for example), tie pins 6, 8 and 9 together. R1 and R2 are not needed in this case.**
- **2. Short Circuit Current, Igc Short Circuit Current, Igc.** *iS* **determined by RgQ. RSC may be chosen with the aid of Figure 12 or the expression:**

$$
R_{SC} \approx \frac{0.6}{I_{SC}} \text{ ohms}
$$

where Igc is measured in amperes. This expression is also valid when current is boosted as shown in Figures 2, 29 and 30.

- **3. Compensation, Cc**
	- A 0.001 μ F capacitor, C_c, from pin 4 to ground will provide **adequate compensation in most applications, with or with**out current boost. Smaller values of C_c will reduce stability **and larger values of Cc will degrade pulse response and out-put impedance versus frequency. The physical location of Cc should be close to the MC1569/MC1469 with short lead lengths.**
-

4. Noise F ilter Capacitor, Cn A 0.1 *flF* **capacitor, Cn, from pin 7 to ground will typically** reduce the output noise voltage to 150 μ V(rms). The value **of Cn can be increased or decreased, depending on the noise voltage requirements of a particular application. A mini**mum value of 0.001 μ F is recommended.

5. Output Capacitor, CQ The value of C0 should be at least 1.0 *jlF* **in order to provide good stability. The maximum value recommended is a function of current limit resistor RSC:**

$$
c_{o(max)} \approx \frac{250 \, \mu \text{F}}{\text{R}_{\text{SC}}}
$$

where R_{SC} is measured in ohms. Values of C_O greater than **this will degrade the pulse response characteristics and increase the settling time.**

6. Shut-Down Control

One method of turning "O FF" the regulator is to apply a dc voltage at pin 2. This control can be used to eliminate power consumption by circuit loads which can be put in "standby" mode. Examples include, an ac ordc "squelch" control for communications circuits, and a dissipation control to protect the regulator under sustained output shortcircuiting (see Figures 34, 39 and 40). As the magnitude of the input-threshold voltage at Pin 2 depends directly upon the junction temperature of the integrated circuit chip, a fixed dc voltage at Pin 2 will cause automatic shut-down for high junction temperatures (see Figure 39). This will protect the chip, independent of the heat sinking used, the ambient temperature, or the input or output voltage levels. Standard logic levels of MRTL, MDTL or MTTL can also be **used to turn the regulator "ON" or "O FF" .**

7. Remote Sensing

The connection to Pin 5 can be made with a separate lead direct to the load. Thus, "remote sensing" can be achieved and the effect of undesired impedances (including that of the milliammeter used to measure I_L) on Z_{out} can be **greatly reduced (see Figure 37).**

OPERATIONS AND APPLICATIONS

This section describes the operation and design of the MCI569 positive voltage regulator and also provides information on useful applications.

SUBJECT SEQUENCE

THEORY OF OPERATION

The usual series voltage regulator shown in Figure 25, consists of a reference voltage, an error amplifier, and a series control element. The error amplifier compares the output voltage with the reference voltage and adjusts the output accordingly until the error is essentially zero. For applications requiring output voltages larger than the reference, there are two options. The first is to use a resistive divider across the output and compare only a fraction of the output voltage to the reference. This approach suffers from reduced feedback to the error amplifier due to the attenuation of the resistive divider. This degrades load regulation especially at high voltage levels.

The alternative is to eliminate the resistive divider and to shift the reference voltage instead. To accomplish this, another amplifier is employed to amplify (or level shift) the reference Voltage using an operational amplifier as shown in Figure 26. The gain-determining resistors may be external, enabling a wide range of output voltages. This is exactly the same approach used in the first option. That is, the output is being resistively divided to match the reference voltage. There is however, one big difference in that the output of this "regulator" is driving the input of another regulator (the error amplifier). The output of the reference amplifier has a relatively low impedance as compared to the input impedance of the error amplifier. Changes in the load of the output of the error amplifier are buffered to the extent that they have virtually no effect on the reference amplifier. If the feedback resistors are external (as they are on the MCI569) a wide range of reference voltages can be established.

The error amplifier can now be operated at unity gain to provide excellent regulation. In fact, this "regulatorwithin-a-regulator" concept permits the load regulation to be specified in terms of output impedance rather than as some percentage change of the output voltage. This approach was used in the design of the MCI569 positivevoltage regulator.

FIGURE 25 - SERIES VOLTAGE REGULATOR FIGURE 26 - THE "REGULATOR-W ITHIN-A-REGULATOR" APPROACH

FIGURE 27 (Recommended External Circuitry is Depicted With Dotted Lines.)

MCI 569 Operation

Figure 27 shows the MCI569 Regulator block diagram, simplified schematic, and complete schematic. The four basic sections of the regulator are: Control, Bias, DC Level Shift, and Output (unity gain) Regulator. Each section is detailed in the following paragraphs.

Control

The control section involves two basic functions, startup and shutdown. A start-up function is required since the biasing is essentially independent of the unregulated

input voltage. It makes use of two zener diodes having the same breakdown voltage. A first or auxiliary zener is driven directly from the input voltage line through a resistor (60 k Ω) and permits the regulator to initially achieve the desired bias conditions. This permits the second, or reference zener to be driven from a current source. When the reference zener enters breakdown, the auxiliary zener is isolated from the rest of the regulator circuitry by a diode disconnect technique. This is necessary to keep the added noise and ripple of the auxiliary zener from degrading the performance of the regulator.

The shutdown control consists of an NPN transistor across the reference zener diode. When this transistor is turned "ON", via pin 2, the reference voltage is reduced to essentially zero volts and the regulator is forced to shutdown. During shutdown the current drain of the complete IC regulator drops to V_{in}/60 k Ω or 500 μ A for a 30 V input.

Bias

A zener diode is the main reference element and forms the heart of the bias circuitry. Its positive temperature coefficient is balanced by the negative temperature coefficients of forward biased diodes in a ratio determined by the resistors in the diode string. The result is a reference voltage of approximately 3.5 Vdc with a typical temperature coefficient of 0.002%/°C. In addition, this circuit also provides a reference current which is used to bias all current sources in the remaining regulator circuitry.

DC Level Shift

The reference voltage is used as the input to a Darlington differential amplifier. The gain of this amplifier is quite high and it therefore may be considered to function as a conventional operational amplifier. Consequently, negative feedback can be employed using two external resistors (R1 and R2) to set the closed-loop gain and to boost the reference voltage to the desired output voltage. A capacitor, C_n , is introduced externally into the level shift network (via pin 7) to stabilize the amplifier and to filter the zener noise. The recommended value for this capacitor is 0.1 μF and should have a voltage rating in excess of the desired output voltage. Smaller capacitors (0.001 μ F minimum) may be used but will cause a slight increase in output noise. Larger values of C_n will reduce the noise as well as delay the start-up of the regulator.

Output Regulator

The output of the level shift amplifier (pin 9) is fed to the noninverting input (pin 6) of the output error amplifier. The inverting input to this amplifier is the Output Sense connection (pin 5) of the regulator. A Darlington connected NPN power transistor is used to handle the load current. The short-circuit current limiting resistor, RSC, is connected in the emitter of this transistor to sample the full load current. By placing an external low-level NPN transistor across R_{SC} as shown in Figure 27, output current can be limited to a predetermined value:

$$
I_{L(max)} \approx \frac{0.6}{R_{SC}}
$$
 or $R_{SC} = \frac{0.6}{I_{L(max)}}$

where $I_{L(max)}$ is the maximum load current (amperes) and R_{SC} is the value of the current limiting resistor (ohms).

Stability and Compensation

As has been seen, the MC1569 employs two amplifiers, each using negative feedback. This implies the possibility of instability due to excessive phase shift at high frequencies. Since the error amplifier is normally used at unity gain (the worst case for stability) a high impedance node is brought out for compensation. For normal operation, a capacitor is connected between this point (pin 4) and ground. The recommended value of $0.001 \mu F$ will insure stability and still provide acceptable transient response (see Figure 28, A and B). It is also necessary to use an output capacitor, C_0 , (typically 1.0 μ F) from the output, V_0 , to ground. When an external transistor is used to boost the current, $C_0 = 1.0 \mu F$ is also recommended (see Figure 2).

TYPICAL NPN CURRENT BOOST CONNECTIONS

FIGURE 29A — 5 Vdc, 10 AMPERE REGULATOR

FIGURE 29B - 5-VOLT 5-AMPERE REGULATOR

NPN CURRENT BOOSTING

For applications requiring more than 500 mA of load current, or for minimizing voltage variations due to temperature changes in the IC regulator arising from changes of the internal power dissipation, the NPN current-boost circuits of Figure 2 or 29 are recommended. The transistor shown in Figure 29A, the 2N3771 (or MJ3771), can supply currents to 10 amperes (subject, of course, to the safe area limitations). To improve the efficiency of the NPN boost configuration, particularly for small output voltages, the circuit of Figure 29 is recommended. An auxiliary 8.5-volt supply is used to power the IC regulator and the heavy load current is obtained from a second supply of lower voltage. For the 10-ampere regulator of Figure 29 this represents a savings of 25 watts when compared with operating the regulator from the single 8.5 V supply. It can supply current to 10 amperes while requiring an input voltage to the collector of the pass transistor of 6.0 volts minimum. The pass transistor is limited to 10 amperes by the added short-circuit current network in its emitter (RSC).

PNP CURRENT BOOSTING

A typical PNP current boost circuit is shown in Figure 30. Voltages from 2.5 Vdc to 37 Vdc and currents of many amperes can be obtained with this circuit.

Since the PNP transistor must not be turned on by the MC1569 bias current (l_b) the resistor R_{in} must meet the following condition:

$$
R_{in} < \frac{V_{BE}}{I_h}
$$

where VBE is the base-to-emitter voltage required to turn on the PNP pass transistor, (typically 0.6 Vdc for silicon and 0.2 Vdc for germanium).

For germanium pass transistors, a silicon diode may be placed in series with the emitter to provide an additional voltage drop. This allows a larger value of Rin than would be possible if the diode were omitted. The diode will, however, be required to carry the maximum load current.

SELF-OSCILLATING SWITCHING REGULATOR

In all of the current boosting circuits shown thus far it has been assumed that the input-output voltage differential can be minimized to obtain maximum efficiency in both the external pass element as well as the MCI569. This may not be possible in applications where only a single supply voltage is available and high current levels preclude zener diode pre-regułating approaches. In such applications a switching-mode voltage regulator is highly desirable since the pass device is either ON or OFF. The theoretical efficiency of an ideal switching regulator is 100%. Realizable efficiencies of 90% are within the realm of possibility thus obviating the need for large power dissipating components. The output voltage will contain a ripple component; however, this can be made quite small if the switching frequency is made relatively high so filtering techniques are effective. Figure 31 shows a functional diagram for a self-oscillating voltage regulator. The comparator-driver will sense the voltage across the inductor, this voltage being related to the load current, I_{L} , by

$$
L\frac{dI_L}{dt} = V.
$$

For a first approximation this can be assumed to be a linear relationship.

Initially, V_0 will be low and Q1 will be ON. The voltage at the non-inverting input will approach $\beta_1 V_{in}$, where:

$$
\beta_1 V_{in} = \frac{V_{ref}R_a}{R_a + R_b} + \frac{V_c R_b}{R_a + R_b}
$$

When this output voltage is reached the comparator will switch, turning Ql OFF. The diode, CR1, will now become forward biased and will supply a path for the inductor current. This current and the sense voltage will start to decrease until the output voltage reaches

$$
\beta_2 V_{in} = \frac{V_{ref} R_a}{R_a + R_b}
$$

where the comparator will again switch turning O1 ON, and the cycle repeats. Thus the output voltage is approximately V_{ref} plus a ripple component.

The frequency of oscillation can be shown to be

$$
f = \frac{V_{out}(V_{in} - V_{out})}{LV_C(I_{max} - I_0)}
$$
(1)

where

 I_{max} = The maximum value of inductor current

 I_{Ω} = The minimum inductor current.

Normally this frequency will be in the range of approximately 2 kHz to 6 kHz. In this range, inductor values can be small and are compatible with the switching times of the pass transistor and diode. The switching time of the comparator is quite fast since positive feedback aids both turn-on and turn-off times. The limiting factors are the diode and pass transistor rise and fall times which should be quite fast or efficiency will suffer.

Figure 32 shows a self oscillating switching regulator which in many respects is similar to the PNP current boost previously discussed. The 6.8 k Ω resistor in conjunction with R1 sets the reference voltage, V_{ref} . Q1 and CR1 are selected for fast switching times as well as the necessary power dissipation ratings. Since a linear inductor is assumed, the inductor cannot be allowed to saturate at maximum load currents and should be chosen accordingly. If core saturation does occur, peak transistor and diode currents will be large and power dissipation will increase.

 I_{max} IL(avg)

FIGURE 31 - BASIC SELF-OSCILLATING SWITCHING REGULATOR

ı,

 c_{o} =

VC

FIGURE 32 - MC1569 SELF-OSCILLATING SWITCHING REGULATOR

As a design center is required for a practical circuit, assume the following requirements:

$$
V_{in} = +28 \text{ Volts}
$$
\n
$$
V_{out} = +10 \text{ Volts}
$$
\n
$$
\Delta V_0 = 50 \text{ mV}
$$
\n
$$
V_{in} = +28 \text{ (s}
$$
\n
$$
V_{out} = +10 \text{ Volts}
$$
\n
$$
V_{in} = +28 \text{ (s}
$$
\n
$$
V_{out} = +10 \text{ V}
$$

Using Equation (1), the inductor value can be found:

L =
$$
\frac{(28-10)}{2(1.125-1)} \frac{10}{28} \left(\frac{1}{5 \times 10^3}\right)
$$

≈7 mH.

For the test circuit, a value of 6 mH was selected. Using POSITIVE AND NEGATIVE POWER
for a first approximation SUPPLIES for a first approximation

$$
C_0 = \frac{(V_{in} - V_{out})(V_{out})}{8 L f^2 V_{in}(\Delta V)}
$$

=
$$
\frac{(28 - 10)^{10}}{8(7 \times 10^{-3})(5 \times 10^3)^2 (28) (50 \times 10^{-3})}
$$

≈95 μF.

As shown, a value of $100 \mu F$ was selected. Since little current is required at pin 6, R_a can be large. Assume R_a = 47 k Ω and then use Equation (2) to determine Rb:

$$
50 \times 10^{-3} = \frac{28}{47 \times \Omega} R_b
$$

$$
R_b = \frac{47}{28} 50 \approx 85\Omega
$$

Since the internal impedance presented by pin 9 is on the order of 60 Ω , a value of R_b = 10 Ω is adequate.

Diodes CR2, CR3, and R_c may be added to prevent saturation of the error amplifier to increase switching speed. When the output stage of the error amplifier approaches saturation, CR2 becomes forward biased and clamps the error amplifier. Resistor R_c should be selected to supply a total of 1 mAdc to CR2 and CR3.

To show correlation between the predicted and tested specifications the following data was obtained:

$$
V_{in} = +28 \text{ (+ 1\%) Volts}
$$

\n
$$
V_{out} = +10 \text{ Volts}
$$

\n
$$
\Delta V_{o} = 60 \text{ mV}
$$

\n
$$
f = 7 \text{ kHz}
$$

\n
$$
\omega 1_{I} = 1 \text{ A}
$$

(2)

which checks quite well with the predicted values. Rb can be adjusted to minimize the ripple component as well as to trim the operating frequency. Also this frequency will change with varying loads as is normal with this type of circuit. Pin 2 can still be used for shut-down if so desired. RSC should be set such that the ratio of load current to base drive current is 10:1 in this case $I_1 \approx 100$ mA and $RSC = 6.5\Omega$.

If the MCI569 is driven from a floating source it is possible to use it as a negative regulator by grounding the positive output terminal. The MCI569 may also be used with the MCI563 to provide completely independent positive and negative voltage regulators with comparable performance.

Some applications may require complementary tracking in which both supplies arrive at the voltage level simultaneously, and variations in the magnitudes of the two voltages track. Figures 3 and 33 illustrate this approach. In this application, the MCI563 is used as the reference regulator, establishing the negative output voltage. The MCI569 positive regulator is used in a tracking mode by grounding one side of the differential amplifier (pin 6 of the MCI569) and using the other side (pin 5 of the MC1569) to sense the voltage developed at the junction of the two 3-k ohm resistors. This differential amplifier controls the MCI569 series pass transistor such that the voltage at pin 5 will be zero. When the voltage at pin 5 equals zero, $+V_0$ must equal $|-V_0|$.

For the configuration shown in Figure 33, the level shift amplifier in the MCI569 is employed to generate an auxiliary +5-volt supply which is boosted to a 2-ampere capability by Q1 and Q2. (The +5-volt supply, as shown, is not short-circuit protected.) The -15-volt supply varies less than 0.1 mV over a zero to —300 mAdc current range and the +15-volt supply tracks this variation. The +15-volt supply varies 20 mV over the zero to +300 mAdc load current range. The +5-volt supply varies less than 5 mV for $0 \leq I_1 \leq 200$ mA with the other two voltages remaining unchanged.

SHUTDOWN TECHNIQUES

Pin 2 of the MC1569 is provided for the express purpose of shutting the regulator "OFF". Referring to the schematic, it can be seen that pin 2 goes to the base of an NPN transistor; which, if turned "ON", will turn the zener "OFF" and deny current to all the biasing current sources. This action causes the output to go to essentially zero volts and the only current drawn by the IC regulator will be the small start current through the 60-k ohm start resistor ($V_{in}/60$ k Ω). This feature provides additional versatility in the applications of the MC1569. Various subsystems may be placed in a "standby" mode to conserve power until actually needed. Or the power may be turned "OFF" in response to other occurrences such as overheating, over-voltage, shorted output, etc.

To activate shutdown, one simply applies a potential greater than two diode drops with a current capability of 1 mA. Note that if a hard supply (i.e., +3 V) is applied directly to pin 2, the shutdown circuitry will be destroyed since there is no inherent current limiting. Maximum rating for the drive current into pin 2 is 10 mA, while 1 mA is adequate for shutdown.

FIGURE 34 - ELECTRONIC SHUT-DOWN USING A MDTL GATE

FIGURE 35 - AUTOMATIC LATCH INTO SHUT-DOWN WHEN OUTPUT IS SHORT-CIRCUITED WITH MANUAL RE-START

FIGURE 36 - VOLTAGE BOOSTING CIRCUIT

Figure 34 shows how the regulator can be controlled by a logic gate. Here, it is assumed that the regulator operates in its normal mode $-$ as a positive regulator referenced to ground $-$ and that the logic gate is of the saturating type, operating from a positive supply to ground. The high logic level should be greater than about 1.5 V and should source no more than 10 mA into pin 2.

The gate shown is of the MDTL type. MRTL and MTTL can also be used as long as the drive current is within safe limits (this is important when using MTTL, where the output stage uses an active pull-up).

In some cases a regulator can be designed which can handle the power dissipation resulting from normal operation but cannot safely dissipate the power resulting from a sustained short-circuit. The circuit of Figure 35 solves this problem by shutting down the regulator when the output is short-circuited.

VOLTAGE BOOSTING

The MCI569 has a maximum output voltage capability of 37 volts which covers the bulk of the user requirements. However, it is possible to obtain higher output voltages. One such voltage boosting circuit is shown in Figure 36.

Since high voltage NPN silicon devices are readily available, the only problem is the voltage limitations of the MCI569. This can be overcome by using voltage shift techniques to limit the voltage to 35 volts across the MCI569 while referencing to a higher output voltage.

The zener diode in the base lead of the NPN device is used to shift the output voltage of the MCI569 by approximately 75 volts to the desired high voltage level, in this case 100 volts. Another voltage shift is accomplished by the resistor divider on the output to accommodate the required 25 volt reference to the MC1569. The 2 $k\Omega$ resistor is used to bias the zener diode so the current through the 4.7 k Ω resistor can be controlled by the MCI569. The 1N4001 diode protects the MCI569 from supplying load current under short circuit conditions and Q2 serves to limit base current to Q1. For R_{SC} as shown, the short circuit current will be approximately 100 mA.

In order to use a single supply voltage, $V_{in}(2)$ can be derived from $V_{in}(1)$ with a zener diode, shunt preregulator.

It can be seen that loop gain has been reduced by the resistor divider and hence the closed loop bandwidth will be less. This of course will result in a more stable system, but regulator performance is degraded to some degree.

REMOTE SENSING

The MCI 569 offers a remote sensing capability. This is important when the load is remote from the regulator, as the resistance of the interconnecting lines $(V₀$ and GND) are added directly to the output impedance of the regulator. By remote sensing, this resistance is included inside the control loop of the regulator and is essentially eliminated. Figure 37 shows how remote sensing is accomplished using both a separate sense line from pin 8 and a separate ground line from the regulator to the remote load.

AN ADJUSTABLE ZERO-TEMPERATURE-COEFFICIENT (0-TC) VOLTAGE REFERENCE SOURCE

The MCI569, when used in conjunction with low TC resistors, makes an excellent reference-voltage generator. If the 3.5 volt reference voltage of the IC regulator is a satisfactory value, then pins 8 and 9 can be tied together and no resistors are needed. This will provide a voltage

reference having a typical temperature coefficient of 0.002%/°C. By adding two resistors, R1 and R2, any voltage between 3.5 Vdc and 37 Vdc can be obtained with the same low TC (see Figure 38).

THERMAL SHUTDOWN

By setting a fixed voltage at pin 2, the MCI569 chip can be protected against excessive junction temperatures caused by power dissipation in the IC regulator. This is based on the negative temperature coefficient of the baseemitter junction of the shutdown transistor and the diode in series with pin 2 (-3.4×10^{-3} V/^oC). By setting 1.0 Vdc externally at pin 2, the regulator will shutdown when the chip temperature reaches approximately +140°C. Figure 39 shows a circuit that uses a zero-TC zener diode and a resistive divider to obtain this voltage.

FIGURE 40 - THERMAL SHUTDOWN WHEN USING

In the case where an external pass transistor is employed, its temperature, rather than that of the IC regulator, requires control. A technique similar to the one just discussed can be used by directly monitoring the case temperature of the pass transistor as is indicated in Figure 40. The case of the normally "OFF" thermal monitoring transistor, Q2, should be in thermal contact with, but electrically isolated from, the case of the boost transistor, Q1.

THERMAL CONSIDERATIONS

Monolithic voltage regulators are subjected to internal heating similar to a power transistor. Since the degree of internal heating is a function of the specific application, the designer must use caution not to exceed the specified maximum junction temperature (+150°C). Exceeding this limit will reduce reliability at an exponential rate. Good heatsinking not only reduces the junction temperature for a given power dissipation; it also tends to improve the dc stability of the output voltage by reducing the junction temperature change resulting from a change in the power dissipation of the IC regulator. By using the derating factors or thermal resistance values given in the Maximum Ratings Table of this data sheet, junction temperature can be computed for any given application in the same manner as for a power transistor*. A shortcircuit on the output terminal can produce a "worst-case" thermal condition especially if the maximum input voltage is applied simultaneously with the maximum value of short-circuit load current. Care should be taken not to

*For more detailed information of methods used to compute junction temperature, see Motorola Application Note AN-226, Measurement of Thermal Properties of Semiconductors.

exceed the maximum junction temperature rating during this fault condition and, in addition, the dc safe operating area limit (see Figure 41).

Thermal characteristics for a voltage regulator are useful in predicting performance since dc load and line regulation are affected by changes in junction temperature. These temperature changes can result from either a change in the ambient temperature, T_A , or a change in the power dissipated in the IC regulator. The effects of ambient temperature change on the dc output voltage can be estimated from the "Temperature Coefficient of Output Voltage" characteristic parameter shown as $\pm 0.002\%/^{\circ}\text{C}$, typical. Power dissipation is typically changed in the IC regulator by varying the dc load current. To estimate the dc change in output voltage due to a change in the dc load current, three effects must be considered:

- 1. junction temperature change due to the change in the power dissipation
- 2. output voltage decrease due to the finite output impedance of the control amplifier
- 3. thermal gradient on the IC chip.

A temperature differential does exist across a power IC chip and can cause a dc shift in the output voltage. A "gradient coefficient," GCV_0 , can be used to describe this effect and is typically -0.06%/watt for the MCI569. For an example of the relative magnitudes of these effects, consider the following conditions:

Given MC1569
with
$$
V_{in} = 10
$$
 Vdc
 $V_0 = 5$ Vdc

and $1_L = 100$ mA to 200 mA

$$
(\Delta I_{\parallel} = 100 \text{ mA})
$$

assume $T_A = 25^{\circ}C$

TO-66 Case with heatsink

assume $\theta_{CS} = 0.2^{\circ}C/W$

and $\theta_{SA} = 2^{O}C/W$

 θ_{JC} = 7.15°C/W (from maximum ratings table)

It is desired to find the ΔV_0 which results from this ΔI_L . Each of the three previously stated effects on V_0 can now be separately considered.

1.
$$
\Delta V_0
$$
 due to ΔT_J
\n
$$
\Delta V_0 = (V_0)(\Delta P_D)(TCV_0)(\theta_{JC} + \theta_{CS} + \theta_{SA})
$$
\nOR
\n
$$
\Delta V_0 = (5 V)(5 V x 0.1 A)(\pm 0.002\% /°C)(9.35°C/W)
$$
\n
$$
\Delta V_0 \approx \pm 0.5 \text{ mV}
$$

2. ΔV_0 due to Z_0

$$
|\Delta V_o| = (-Z_o)(I_L)
$$

$$
|\Delta V_o| = -(2 \times 10^{-2})(10^{-1}) = -2 \text{ mV}
$$

3. ΔV_o due to gradient coefficient, GCV_o

$$
|\Delta V_o| = (GCV_o)(V_o)(\Delta P_D)
$$

\n
$$
|\Delta V_o| = (-6 \times 10^{-4}/W)(5 \text{ volts})(5 \times 10^{-1}W)
$$

\n
$$
|\Delta V_o| = -1.6 \text{ mV}
$$

Therefore the total ΔV_{Q} is given by

$$
|\Delta V_0 \text{ total}| = \pm 0.5 - 2.0 - 1.6 \text{ mV}
$$

-4.1 mV $\leq |V_0 \text{ total}| \leq -3.1 \text{ mV}$

Other operating conditions may be substituted and computed in a similar manner to evaluate the relative effects of the parameters.
